Arterial end-to-side grafting in coronary artery bypass grafting: the Tector procedure

Background. The current treatment of choice in patients with three-vessel coronary disease is coronary artery bypass grafting. The use of the left internal mammary artery in bypass grafting has shown superior long-term outcomes compared with venous grafting. In our study we assess the safety and feasibility of all-arterial coronary artery bypass graft surgery using the procedure as described by Tector et al. in 2001.

Methods. Between June 2001 and February 2007, we studied 133 patients eligible for non-emergency surgical revascularisation. Primary endpoints were death or re-infarction within a 30-day period. Secondary endpoints were the need for emergency coronary surgery, angioplasty and mediastinitis. Long-term follow-up had a mean duration of 33 months postoperatively.

Results. All 133 patients were successfully revascularised, 98% with the off-pump technique. In 93% of the patients (n=124) full arterial grafting was achieved using both internal mammary arteries. Thirty-day mortality was 1.5% (n=2), ten re-thoracotomies were performed, one myocardial infarction and one case of mediastinitis were reported. In the next four years six additional patients died. Most of these deaths were due to non-cardiovascular causes. Two patients required angioplasty because of distal bypass graft failure and one for new native coronary artery disease.

Conclusion. All-arterial bypass grafting using both internal mammary arteries with the technique as described by Tector is safe and feasible without excess deep sternal wound infections. Late major adverse cardiac events are rare and due to distal graft dysfunction, which can be treated by percutaneous coronary intervention. (Neth Heart J 2010;18:7-11.)

Keywords: coronary artery disease; bypass grafting; angina; all arterial revascularisation; off-pump CABG

Coronary artery disease is the main cause of death in the Western world. The current treatment of choice in patients with complex three-vessel disease is coronary artery bypass grafting (CABG). This procedure is performed using both arterial and venous grafts. A major concern regarding the use of venous grafts is graft failure. This leads to a higher risk of recurrent angina, new myocardial infarction and the necessity of renewed interventions.1,2

Currently, many efforts are put into the comparison of bypass surgery with drug-eluting stenting to overcome the potential hazards and graft failures after CABG. The initial one-year follow-up results of the SYNTAX trial3 do not show a superiority of one of these techniques despite the fact that all the patients in the surgery group had been grafted with venous material and the left internal mammary artery (LIMA). Earlier, the ARTS trial4 found a need for revascularisation of 7% at three years of follow-up.

Coronary bypass grafting with the use of the LIMA has shown superior long-term outcomes compared with CABG with only venous grafts5,6 with respect to patency and reduced ischaemia rates. However, total arterial revascularisation was limited by technical difficulties. In 2001 Tector et al.7 described a technique in which both intra-thoracic arteries are used as grafts, making it possible to acquire full arterial revascularisation. Total arterial revascularisation may be con-
Arterial end-to-side grafting in coronary artery bypass grafting: the Tector procedure

Methods
From June 2001 to February 2007, 799 patients were referred from the Alkmaar Medical Centre to the VU Medical Centre, Amsterdam, for coronary artery bypass grafting. Of the 208 patients operated by one surgeon, 133 received a Tector procedure (16.7%). This procedure was attempted on all non-emergency patients under 70 years of age; it was also attempted on older patients without suitable venous graft material or with general arteriosclerotic disease in order to prevent aortic clamping. Our primary endpoints were death or re-infarction within a 30-day period. Secondary endpoints were the need for emergency coronary surgery, angioplasty and mediastinitis. Preoperative risk was assessed for all patients using Euroscore ratings.8,9 Patient follow-up was done up until four years postoperatively in our outpatient clinic in Alkmaar.

Tector procedure
All procedures were carried out by one experienced surgeon (E.K.J.) and planned as an off-pump procedure. Both mammary arteries were dissected, leaving a small pedicle surrounding the arteries.

The free right internal mammary artery (FRIMA) graft is attached to the LIMA as a T graft (end to side) slightly distal from the site where the LIMA enters the pericardial cavity, just where it crosses the main pulmonary artery. The T graft anastomosis, approximately 8 mm long, is constructed using a running stitch with 8-0 monofilament suture. This T graft has an average length of 18 to 20 cm. Anterior revascularisation was performed first, using the LIMA to revascularise the left anterior descending coronary artery (LAD). The diagonal branches are bypassed either with the LIMA or FRIMA, depending on the anatomy. Subsequently, anastomoses to the lateral, posterior and inferior parts were made with the FRIMA (figure 1).

Results
Patients
In the six-year period studied, 133 consecutive patients (107 men and 26 women) underwent coronary artery bypass grafting with the intention of total arterial coronary bypass grafting. The patients had a mean age of 67±11 years and 17% had known diabetes. All patients had symptomatic multivessel coronary artery disease, 66% were operated on for an acute coronary syndrome and 41% had experienced a previous myocardial infarction, while four patients underwent previous coronary artery bypass surgery. The majority of the patients had a preserved left ventricular function. The mean preoperative Euroscore and log Euroscore were 3.7 (95% CI 3.2 to 4.2) and 4.5 (95% CI 3.4 to 5.5) respectively (table 1).

Operation
All patients were scheduled for a total arterial revascularisation according to the Tector technique. In all but one patient, the LIMA was used as the primary arterial graft. The remaining patient already had a patent LIMA anastomosed to the LAD at his first operation. The FRIMA was additionally used in all but one patient. The bypass operation could be performed without cardiopulmonary bypass in 98% of the patients. In three procedures it was necessary to convert to on-pump surgery due to haemodynamic instability. All patients were successfully revascularised (i.e. all preoperative planned anastomoses were successfully placed) and left the operating suite alive. Total arterial revascularisation was successful in 93%, while in nine patients (7%) additional venous grafts were needed as arterial grafts had insufficient length to
allow for complete revascularisation. The number of proximal and distal anastomoses is given in table 2.

Thirty-day follow-up
In the 30-day follow-up period, two deaths (1.5%) were registered. One death was an 84-year-old male with a recent myocardial infarction, impaired left ventricular function and absent venous graft material, who died in the intensive care unit within 24 hours after the procedure, due to persistent cardiac failure. One death was a 73-year-old male with an uneventful recovery who was treated with acenocoumarol for atrial fibrillation. On the 17th day after the procedure he suffered a haematothorax that required resuscitation and a re-exploration. No active bleeding was found. The patient died 26 days after the procedure due to irreversible neurological damage. Only one patient (0.8%) suffered a postoperative myocardial infarction necessitating percutaneous intervention of the LIMA and FRIMA bypass graft.

Late follow-up
All patients had a long-term follow-up with a median duration of 33 (1 to 74) months. After the initial hospitalisation period, six additional patients died. All of these deaths were non-cardiovascular; two died in a nursing home due to advanced age, two had a fatal CVA, one died following a trauma and one patient died in a diabetic coma. None of the patients suffered a myocardial infarction after their hospital discharge and repeat cardiovascular surgery was not necessary. Two patients were treated with percutaneous coronary intervention for late bypass graft dysfunction. In both patients the distal FRIMA graft was diseased and dysfunctional (at 13 and 19 months postoperatively). Both underwent successful PCI with stenting of the right coronary artery, with good long-term results.

CVA=cerebral vascular accident, CABG=coronary artery bypass graft.

One patient had a percutaneous coronary intervention for new native coronary artery disease (table 4).

Discussion

Total arterial coronary bypass grafting using the Tector technique seems safe and is a feasible approach to treat multi-vessel coronary artery disease with a success of 98% at 30-day follow-up with two deaths and one myocardial infarction necessitating PCI. At late follow-up two patients had a PCI procedure for FRIMA graft dysfunction and one for new native coronary artery disease. These safety results are comparable with the 2.3% 30-day mortality described by Tector and colleagues and the 2% overall in-hospital mortality found by Baskett et al. in a study of 71,470 patients undergoing CABG. Therefore, total arterial coronary bypass grafting using the Tector technique seems safe and is a feasible approach to treat multi-vessel coronary artery disease.

Arterial revascularisation

As early as the 1970s, reports were published that support the eligibility of arterial coronary bypasses over the use of venous grafts with regard to patency. An early recognised concern with venous grafts is graft failure, which may occur at two time intervals: either early failure due to technical difficulties or late failure due to progressive atherosclerosis of especially venous grafts or native coronary arteries. However, total arterial coronary bypass grafting has eluded surgeons for several decades due to technical difficulties. For example, the use of internal mammary arteries is limited by its anatomy. The LIMA has a limited range; particularly the inferior and posterior parts of the heart cannot be reached. Different techniques exist to achieve complete arterial revascularisation. Among others, the use of the radial artery and gastro-epiploic artery have been proposed. Various studies, however, showed improved survival rates and a smaller need for revascularisation when using both the internal mammary arteries.

This procedure uses the RIMA as a free graft (FRIMA) which is subsequently anastomosed end-to-side to the LIMA. This enables surgeons to locate the FRIMA approximately 10 cm closer to the inferior and posterior superficial coronary arteries, making full arterial revascularisation possible for most patients with the use of internal thoracic arteries only.

Off-pump surgery

Another advantage of this Tector series was the opportunity to use an off-pump operation technique, which may facilitate a faster recovery. Off-pump coronary artery bypass surgery may overcome the unwanted effects of the use of cardiopulmonary bypass which induces whole body inflammation, generates micro-embolism and the need to cross-clamp the atheromatous aorta. Therefore, if cardiopulmonary bypass can be avoided, a reduced postoperative morbidity and mortality rate may be expected. Several randomised studies have indeed shown that off-pump bypass surgery is equally safe with similar complete revascularisation rates as standard bypass surgery with a reduced enzyme release, a reduced length of stay, improved short-term cognitive recovery and reduced major adverse cardiac events (MACE) rate. This in turn results in lower costs.

Favourable results of off-pump CABG may particularly become apparent in high-risk patients: advanced age, diabetics, acute myocardial infarction and patients with an atheromatous aorta. Patients may achieve excellent results after either type of coronary bypass surgery. Individual outcomes likely depend on other factors as well, such as the skill of the surgeon, the quality of the institution and the availability of quality programmes such as critical pathways. These elements also apply to our series: a delicate cooperation between two hospitals, using dedicated surgeons and critical pathway led by a nurse practitioner, led to a successful arterial revascularisation programme with excellent short-term and mid-term outcomes.

Limitations

We aimed to describe the safety and feasibility of this technique in a collaboration between two teaching hospitals. It is a relatively small population, with exclusion of emergency surgery. It is, however, a representative sample of our outpatient clinic population, including diabetics.

We describe a short period of follow-up with relatively good results with respect to death and occurrence of myocardial infarction. It would be of interest to follow this population for a longer period of time and compare them with conventional CABG. We have made no attempt to study graft patency, which is an extremely important component of the safety and efficacy of coronary artery bypass for any patient population. Puskas et al. showed early graft patency rates equal to literature data for on-pump procedures. If a difference in long-term patency rates between
on- and off-pump existed, it should be evident in early and midterm results.

Conclusion
All-arterial bypass grafting using both internal mammary arteries with the technique as described by Tector is safe and feasible without excess deep sternal wound infections. Late major adverse cardiac events are rare due to distal graft dysfunction, which can be treated by percutaneous coronary intervention.
